Hash Code in Java

In Java, a hashcode is an integer value associated with an object. It is generated using the `hashCode()` method, which is defined in the `Object` class and is inherited by all Java classes.

The main purpose of generating a hash code is to identify and locate objects quickly when using hash-based collections such as `HashMap`, `HashSet` and `Hashtable`. When an object is added to a hash-based collection, Java uses its `hashCode` to determine where the object ~~the~~ should be stored. When searching for the object, the hash code helps Java find it quickly instead of checking every object.

Eg: class Student {

int rollNo;

Student(int rollNo) {

this.rollNo = rollNo;

}

}

public class main {

public static void main (String[] args) {

Student s1 = new Student(101);

```
System.out.println("Hash code : " + s1.hashCode());  
}
```

```
}
```

o/p: Hash code : 12345678

The actual hash code value may be
different each time.
